Abstract

Influenza is a major cause of hospitalization in all age groups. Cardiovascular complications due to influenza are important causes of morbidity and mortality in the US, especially in the elderly population (aged more than 65 years). Acute Myocardial Infarction (AMI) is the most serious among the cardiovascular causes of mortality following the attack of influenza, mainly in patients with various co-morbidities like pre-existing coronary artery disease (CAD), diabetes mellitus (DM), hypertension (HTN) and heart failure (HF). We have reviewed the association between influenza virus infection and AMI and extrapolated the beneficial effects of influenza vaccine in preventing AMI and its grave consequences.

Key words: Acute myocardial infarction, influenza, influenza vaccine

Introduction

Influenza complications are important causes of morbidity and mortality in many parts of the world, especially in the elderly population (aged > 65 years). This seems to be on an increasing trend with the increase in life expectancy in the aging population1. Acute Myocardial Infarction (AMI) is the leading cardiovascular complication of influenza virus infection more importantly in the elderly and the high-risk individuals2-4. According to the data from CDC-Influenza Hospitalization Surveillance Network, there were 30,453 laboratory-confirmed influenza-related hospitalizations between October 2017 and April 2018. The majority (58%) of influenza-associated hospitalizations were in the elderly age group5. Younger patients (age < 65 years) were at risk of influenza-related complications only in the setting of high-risk factors such as immune-compromised states, coronary artery disease (CAD), heart failure (HF) exacerbations, hypertension (HTN) and diabetes mellitus (DM)6. The purpose of this article is to provide an updated review on the potential of influenza virus infection as a trigger for AMI and the role of vaccination in the prevention of AMI associated hospitalization and mortality and also to highlight the key areas where further research is warranted.

Materials and methods

Data extraction

We searched Medline and Embase using relevant Medical Subject Headings (MeSH) termed influenza or influenza virus or flu or flu vaccine and myocardial infarction or acute myocardial infarction or STEMI/ACS or heart attack literature published within the last five years with additional filters of human studies and customized articles. The titles and abstracts of all results were reviewed and studies...
were selected for full-text analysis according to their eligibility criteria.

**Eligibility criteria**
We included human studies on AMI and influenza or influenza vaccination in adults (age more than or equal to 18 years) for full-text analysis. We excluded review articles and case reports.

**Outcomes of interest**
The primary outcome was AMI triggered by influenza, including AMI hospitalizations and mortalities. The role of vaccination in the prevention of the above concomitances was examined in the secondary outcome analysis.

**Quality assessment and data extraction**
Authors NBs and SS independently performed the study selection, data extraction and quality assessment.

**Study characteristics**
The search using the appropriate MeSH terms yielded 1405 articles out of which 112 were relevant and fulfilled our eligibility criteria. From these, we excluded 99 articles and included only 13 for the discussion according to the homogeneity of these studies with ours (Flow chart depicted below). We included data from CDC and other important studies for the references. We also included high-quality meta-analysis for the discussion regarding the role of influenza vaccination in the prevention of AMI associated hospitalization and death.

**Discussion**

Prevalence of influenza triggered AMI
Influenza is a trigger for AMI and ischemic heart disease (IHD) particularly in the elderly population. Warren-Gash et al. performed a multicentre prospective time series study in England, Wales and Hong Kong and found that influenza was associated with increased AMI related hospitalization and death, suggesting this infection as an independent risk factor for AMI. This is further supported by an observational study by Song et al. who too reported that elderly patients suffering from influenza and having other comorbidities such as DM, HF, pre-existing CAD and HTN had higher in-hospital cardiac mortality (fatal cardiac arrest and ventricular arrhythmias) as compared to patients without these risk factors.

A similar association between infection due to influenza virus and AMI was documented by Pearce et al. and Kwong et al. Kwong et al. further
substantiated that the influenza virus was a stronger risk factor for the development of AMI than any other virus causing acute respiratory tract infection. A time series study by Nguyen et al. found that there was a significant increase in all cause cardiovascular mortality and AMI mortality during the influenza outbreak.

Guan and colleagues in the recent past stated that cases of AMI were more likely to have positive IgG antibodies to influenza virus A and B as compared to controls; an observation which supported the hypothesis that previous influenza virus infection had a role to play in the development of atherosclerosis, eventually triggering the occurrence of AMI.

Pathogenesis of post-influenza AMI
The precise mechanism for the development of AMI following influenza virus infection is unclear. However, Naghavi et al. proposed that the virus promoted atherosclerotic plaque formation by inducing inflammation, smooth muscle cell proliferation and fibrin deposition. Histological analysis from the aortic sections of apolipoprotein E-deficient mice injected with influenza A virus showed marked proliferation of intimal epithelial cells along with smooth muscle cells of tunica media, which were filled with macrophages and T lymphocytes, quite suggestive of atherosclerosis.

Notwithstanding the above, the exact link between the formation of atherosclerotic plaque and influenza infection has not been clearly delineated. MacIntyre et al. recently proposed that influenza potentiated the release of inflammatory cytokines which could give rise to a prothrombotic state. Further, influenza might have a direct effect on the heart, producing local inflammatory changes, as evidenced by histopathological and molecular studies on influenza-infected mice. Thus, a series of studies conducted in the recent past, at various centres supported the above-mentioned hypothesis and these data have been presented vide Table 1.

Further studies are, however, needed to shed light on this fascinating aspect of the pathogenesis of AMI happening as a sequel of infection due to influenza virus.

Can influenza vaccination prevent AMI and its complications?

The proposed solution to prevent the AMI hospitalizations and mortality following an attack of influenza is prompt administration of influenza vaccine. Huang et al. conducted a cohort study and showed a significant reduction in the risk of ischemic heart disease in elderly patients receiving influenza vaccine19. A systematic review by Clar et al. also showed that AMI was significantly reduced after influenza vaccination20. In a prospective randomized open-ended study by Phrommintikul et al., influenza vaccination was shown to decrease major cardiovascular hospitalizations due to AMI. However, no significant difference was found in the incidence of cardiovascular deaths among vaccine recipient and non-recipient groups21. This is further supported in a meta-analysis by Udell et al., who reported that 42 of 3238 high risk patients (1.3%) died of cardiovascular cause within one year of being treated with influenza vaccine compared with 55 of 3231 high risk patients (1.7%) treated with placebo (RR, 0.81 [95% CI, 0.56-1.38]; P = 0.61; F = 68%). As the difference is statistically non-significant, further studies are warranted to prove the benefit of influenza vaccine in the prevention of cardiovascular mortality, especially in high-risk patients with previous acute coronary syndrome22. However, vaccine, by preventing influenza and its associated hospitalizations, in a way could prevent the possibility of AMI triggered by the mechanisms discussed above and also might prevent the associated AMI related mortality.

In the light of the aforementioned ambiguity on the effect of administration of influenza vaccine on the prevention of AMI and its clinical outcome, it could, thus, be advocated that further randomized control trials would be needed to provide strong evidences supporting the beneficial role of vaccination against influenza in the prevention of cardiovascular mortality. Consistent with the above, a major multicentre prospective randomized control trial entitled, ‘Influenza Vaccination after Myocardial Infarction (IAMI Trial) NCT02831608’, based on the Swedish Angiography and Angioplasty Registry (SCAAR) platform is ongoing to give us the insight on in-hospital influenza vaccination and cardiovascular outcomes in patients with AMI23.

Conclusions

Many studies in the past put forth the view that influenza virus infection was a trigger for AMI24. Though the role of influenza virus in the initiation of AMI was proven by a number of investigations and the risk for AMI was found to be higher with infection due to influenza virus as compared to those due to other respiratory viruses1, yet data exhibiting concrete evidences in favour of the causal role of the influenza virus in giving rise to AMI are still lacking. Influenza vaccination could play a protective role in the occurrence of influenza-associated hospitalization and mortality due to AMI. Hence, vaccination should be encouraged to prevent cardiovascular complications and mortality especially among high-risk and elderly patients20-25.
